

CMPU 100 · Programming with Data

Expressions, Values, and Names

Class 2

A *program* instructs a computer to do something.

For the computer to carry out these instructions, they need to be *precise*.

But programs also need to be understood by people, so they need to be *readable*!

We write a program in a *programming language* and we run it in a *programming environment*.

The Most Popular Programming Languages

Share of the most popular programming languages in the world*

```
class HelloWorldApp {  
    public static void main(String[] args) {  
        System.out.println("Hello, world!");  
    }  
}
```

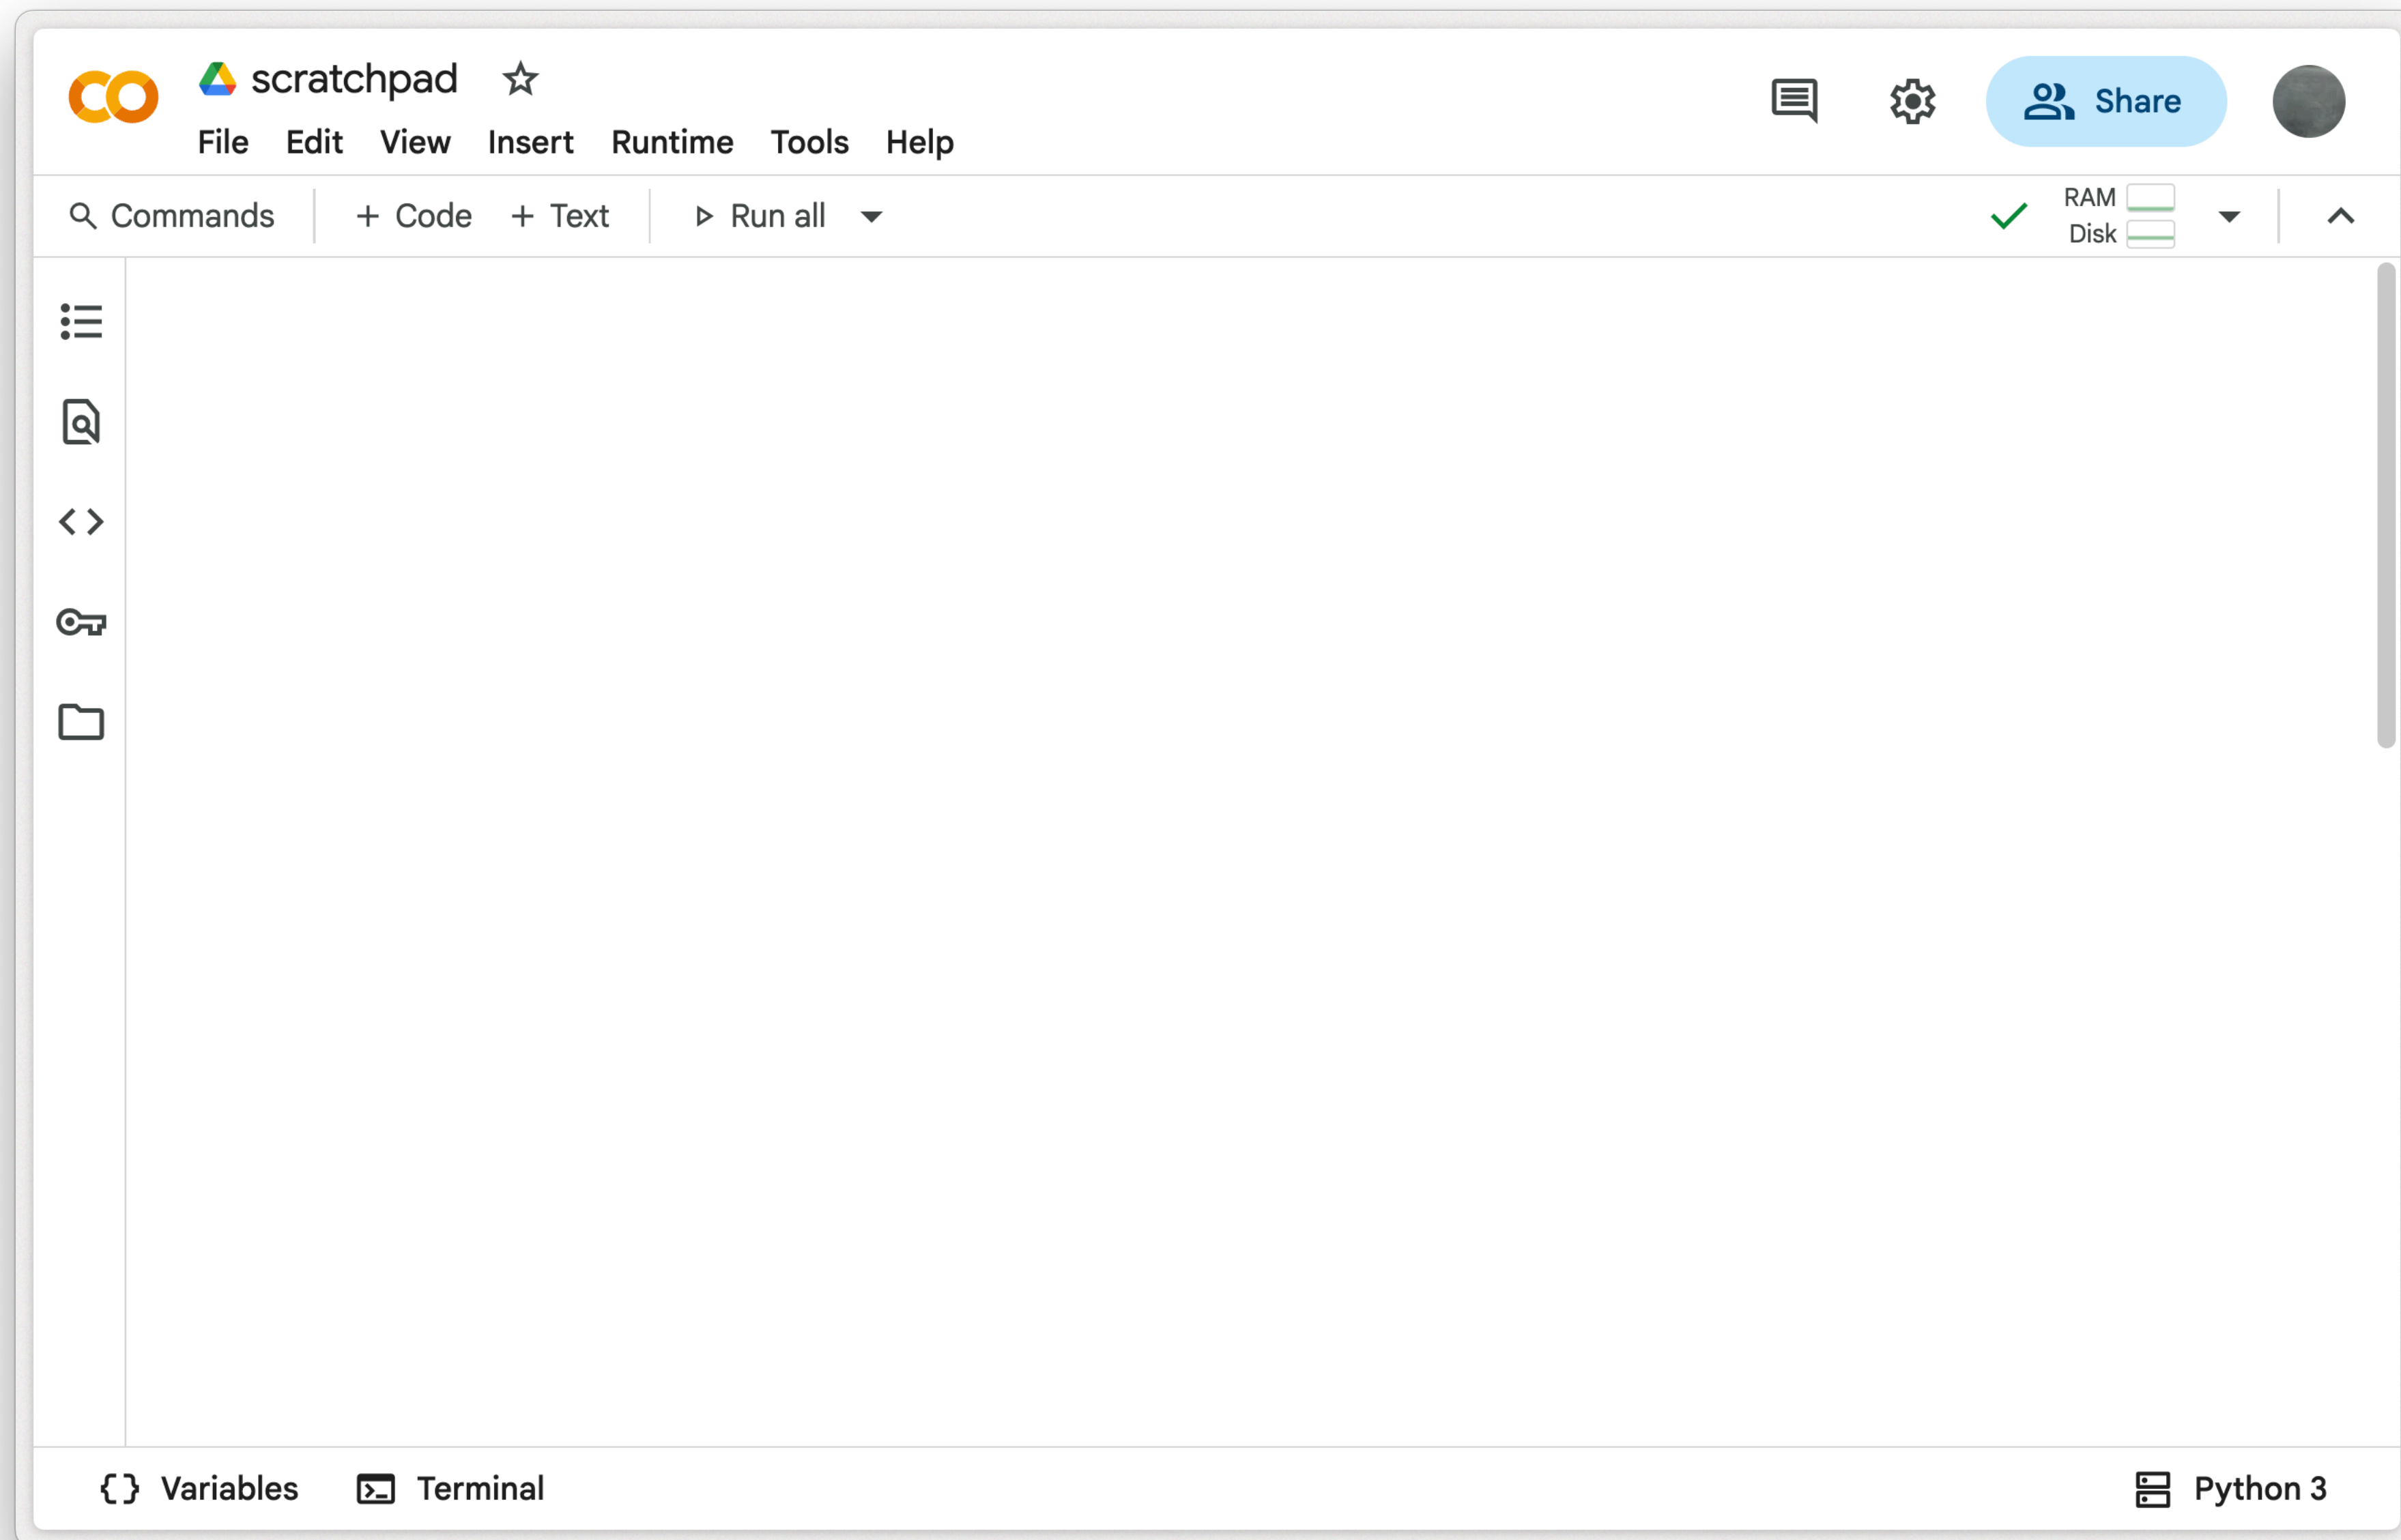

```
class HelloWorldApp {  
    public static void main(String[] args) {  
        System.out.println("Hello, world!");  
    }  
}
```

```
print("Hello, world!")
```

This is a code cell.

Jupyter notebooks are quite recent – they're the hot format for work in data science – but the idea of interleaving text with code dates back to Donald Knuth's introduction of *literate programming* in 1984.

To start with, you can think of Python like a calculator.

Calculators take *expressions* and compute *values*.

Calculators take *expressions* and compute *values*.

Calculators take *expressions* and compute *values*.

17  17

Calculators take *expressions* and compute *values*.

17  17

-1 + 3.14

Calculators take *expressions* and compute *values*.

17  17

-1 + 3.14  2.14

Calculators take *expressions* and compute *values*.

17  17

-1 + 3.14  2.14

2 ** 3

Calculators take *expressions* and compute *values*.

17  17

-1 + 3.14  2.14

2 ** 3  8

Calculators take *expressions* and compute *values*.

17  17

-1 + 3.14  2.14

2 ** 3  8

(17 - 14) / 2

Calculators take *expressions* and compute *values*.

17  17

-1 + 3.14  2.14

2 ** 3  8

(17 - 14) / 2  1.5

$(3 + 4) * (5 + 1)$ is an *expression* – a computation that produces an answer.

A program just consists of one or more computations you want to run.

An individual number like **17** is a *value* – it can't be computed any further.

Mathematical expressions in Python use the same *order of operations* that you learned in school (PEMDAS):

$60 / 2 * 3 \rightarrow 90.0$

$60 / (2 * 3) \rightarrow 10.0$

Whenever you're not sure which operator is evaluated first – or you want to fix a certain order – use *parentheses*.

Call expressions

$f(42)$

*What function
to call*

f(42)

*What function
to call*

*Argument to
the function*

f(42)

The diagram illustrates the components of a function call. Two boxes at the top, labeled 'What function to call' and 'Argument to the function', have arrows pointing to the 'f' and '42' in the expression 'f(42)' respectively. The 'f' and '42' are each enclosed in a red square box.

*What function
to call*

*Argument to
the function*

f(**42**)

“Call f on 42.”

*What function
to call*

*First
argument*

*Second
argument*

max(**13**, **42**)

```
graph TD; A["What function to call"] --> B["max"]; C["First argument"] --> D["13"]; E["Second argument"] --> F["42"]
```

`max(13, 42)`

42

Sometimes the same computation can be done with an operator or a function, e.g.,

```
10 ** 2
```

```
100
```

```
pow(10, 2)
```

```
100
```

<i>Call expression format</i>	<i>Return value</i>
<code>min(<i>arg</i>₁, <i>arg</i>₂, ...)</code>	Minimum value out of two or more arguments
<code>max(<i>arg</i>₁, <i>arg</i>₂, ...)</code>	Maximum value out of two or more arguments
<code>abs(<i>arg</i>)</code>	Absolute value of the provided argument
<code>pow(<i>base</i>, <i>exponent</i>)</code>	Base number raised to the exponent
<code>round(<i>number</i>, <i>precision</i>)</code>	Round the number to the specified number of decimal places

Tuberculosis — United States, 2021

Weekly / March 25, 2022 / 71(12);441–446

[Print](#)

Thomas D. Filardo, MD^{1,2}; Pei-Jean Feng, MPH²; Robert H. Pratt²; Sandy F. Price²; Julie L. Self, PhD² ([VIEW AUTHOR AFFILIATIONS](#))

[View suggested citation](#)

Summary

What is already known about this topic?

The number of reported U.S. tuberculosis (TB) cases decreased sharply in 2020, possibly related to multiple factors associated with the COVID-19 pandemic.

What is added by this report?

Reported TB incidence (cases per 100,000 persons) increased 9.4%, from 2.2 during 2020 to 2.4 during 2021 but was lower than incidence during 2019 (2.7). Increases occurred among both U.S.-born and non-U.S.-born persons.

What are the implications for public health practice?

Factors contributing to changes in reported TB during 2020–2021 likely include an actual reduction in TB incidence as well as delayed or missed TB diagnoses. Timely evaluation and treatment of TB and latent tuberculosis infection remain critical to achieving U.S. TB elimination.

Numbers

2 + 3

5

10 / 2

5.0

Why is Python displaying the same number two ways?

What we saw were two different *data types* used for numbers in Python:

Integers

Floating-point numbers

-10.1

-10

0

0.0

1.0

6.55

7

What we saw were two different *data types* used for numbers in Python:

Integers are whole numbers

Floating-point numbers

-10.1

-10

0

0.0

1.0

6.55

7

What we saw were two different *data types* used for numbers in Python:

Integers are whole numbers

Floating-point numbers have a decimal point

-10.1

-10

0

0.0

1.0

6.55

7

Adding subtracting, and multiplying integers always gives you another integer.

But if there's any floating-point number, the result is another float – even if the decimal part is zero!

`3 + (2 ** 9) - 15 * 14 + 1 → 306`

`3 + (2 ** 9) - 15 * 14 + 1.0 → 306.0`

Division (/) *always* results in a float since the result isn't guaranteed to be a whole number:

$$15 / 3 \rightarrow 5.0$$

When performing calculations with floating-point numbers, you'll sometimes see a small amount of *error* in the result:

	0.1 + 0.1
→	0.2

	0.1 + 0.2 + 0.3
→	0.600000000000000000000001

This is a consequence of how Python internally represents floats. There's nothing for you to do about it except be aware!

If you're curious about the details of that representation, you can [read more about it](#).

String values

Text *strings* are values consisting of a sequence of characters (letters, numbers, punctuation, emoji, etc.):

```
"Poughkeepsie"  
'New York'
```

Strings can be written between either single or double quotes.

You can *concatenate* (combine) strings using the + operator:

	<code>"Hello," + " " + "world!"</code>
<code>→</code>	<code>"Hello, world!"</code>

And you can use the **len** function to ask for the *length* of a string – how many characters are in it:

	<code>len("Hello")</code>
→	5

Working with different types of values

Operations may only work on certain types of data!

The same operator or function may work differently when it's given different types of data as input

```
3 + 4
```

```
"3" + "4"
```

The same operator or function may work differently when it's given different types of data as input

	3 + 4
→	7

"3" + "4"

The same operator or function may work differently when it's given different types of data as input

	3 + 4
→	7

	"3" + "4"
→	"34"

The same operator or function may work differently when it's given different types of data as input

3 * 4

"3" * 4

The same operator or function may work differently when it's given different types of data as input

	3 * 4
→	12

"3" * 4

The same operator or function may work differently when it's given different types of data as input

	3 * 4
→	12

	"3" * 4
→	"3333"

The same operator or function may work differently when it's given different types of data as input

```
max(3, 4)
```

```
max("three", "four")
```

The same operator or function may work differently when it's given different types of data as input

```
max(3, 4)
```

```
4
```

```
max("three", "four")
```

The same operator or function may work differently when it's given different types of data as input

```
max(3, 4)
```

→

4

```
max("three", "four")
```

→

"three"

Prest-o change-o

When it makes sense, we can
typecast – convert values
between data types.

Prest-o change-o

When it makes sense, we can *typecast* – convert values between data types.

Prest-o change-o

When it makes sense, we can *typecast* – convert values between data types.

	<code>int(3.92)</code>
→	3
	<code>int("-5")</code>
→	-5

Prest-o change-o

When it makes sense, we can *typecast* – convert values between data types.

```
int(3.92)
```

→

```
3
```

```
int("-5")
```

→

```
-5
```

```
int("4.1")
```

Prest-o change-o

When it makes sense, we can *typecast* – convert values between data types.

	<code>int(3.92)</code>
→	3
	<code>int("-5")</code>
→	-5
	<code>int("4.1")</code>
→	Error!

Prest-o change-o

When it makes sense, we can
typecast – convert values
between data types.

Prest-o change-o

When it makes sense, we can
typecast – convert values
between data types.

Prest-o change-o

When it makes sense, we can *typecast* – convert values between data types.

	<code>float(3)</code>
→	<code>3.0</code>
	<code>float("3.14")</code>
→	<code>3.14</code>

Prest-o change-o

When it makes sense, we can
typecast – convert values
between data types.

```
str(13 + 14 + 15/2)
```

Prest-o change-o

When it makes sense, we can
typecast – convert values
between data types.

→

<code>str(13 + 14 + 15/2)</code>
<code>"34.5"</code>

How does something like $(4 + 2) / 3$ work?

What is the operator $/$ dividing?

Shouldn't $/$ expect two numbers?

Even though $(4 + 2)$ isn't a number, it's an expression that *evaluates* to a number.

This works for all data types, not just numbers!

When we write complex expressions, Python evaluates them from the inside out:

```
7 + (6 / (1 + 1))
```

When we write complex expressions, Python evaluates them from the inside out:

$7 + (6 / (1 + 1))$
$\rightarrow 7 + (6 / 2)$

When we write complex expressions, Python evaluates them from the inside out:

	$7 + (6 / (1 + 1))$
→	$7 + (6 / 2)$
→	$7 + 3$

When we write complex expressions, Python evaluates them from the inside out:

	$7 + (6 / (1 + 1))$
→	$7 + (6 / 2)$
→	$7 + 3$
→	10

When we write complex expressions, Python evaluates them from the inside out:

```
max(4, min(1, 9))
```

When we write complex expressions, Python evaluates them from the inside out:

```
max(4, min(1, 9))
```

This isn't a value, so we need to evaluate this function call before we can evaluate the call to max.

When we write complex expressions, Python evaluates them from the inside out:

```
max(4, min(1, 9))
```

```
max(4, 1)
```

When we write complex expressions, Python evaluates them from the inside out:

	<code>max(4, min(1, 9))</code>
→	<code>max(4, 1)</code>
→	<code>4</code>

We can nest as many function calls as we want!

```
min(abs(max(-1, -2, -3, min(4, -2))), max(5, 100))
```

We can nest as many function calls as we want!

```
min(abs(max(-1, -2, -3, min(4, -2))), max(5, 100))
```

We can nest as many function calls as we want!

```
min(abs(max(-1, -2, -3, min(4, -2))), max(5, 100))
```

→

```
min(abs(max(-1, -2, -3, min(4, -2))), 100)
```

We can nest as many function calls as we want!

```
min(abs(max(-1, -2, -3, min(4, -2))), max(5, 100))
```

→

```

Defining names

$$x = 5$$

$x = 5$

The name x is bound to the value 5, like putting a baggage tag on a suitcase.

$x = 5$

$y = 1 + 2 * 3 - 8 / 2$

*First Python evaluates the
right-hand expression...*

$$x = 5$$

$$y = 1 + 2 * 3 - 8 / 2$$

$$\rightarrow y = 1 + 6 - 8 / 2$$

*First Python evaluates the
right-hand expression...*

$$x = 5$$

$$y = 1 + 2 * 3 - 8 / 2$$

$$\rightarrow y = 1 + 6 - 8 / 2$$

$$\rightarrow y = 7 - 4$$

*First Python evaluates the
right-hand expression...*

$$x = 5$$

$$y = 1 + 2 * 3 - 8 / 2$$

$$\rightarrow y = 1 + 6 - 8 / 2$$

$$\rightarrow y = 7 - 4$$

$$\rightarrow y = 3$$

*First Python evaluates the
right-hand expression...*

$$x = 5$$

$$y = 1 + 2 * 3 - 8 / 2$$

$$\rightarrow y = 1 + 6 - 8 / 2$$

$$\rightarrow y = 7 - 4$$

$$\rightarrow y = 3$$

First Python evaluates the right-hand expression...

...then it binds the name `y` to the resulting value.

Several names may have the same value:

<i>seven</i> = 7 seven
7

<i>septem</i> = 7 septem
7

Assignment statements are *not* mathematical equations.

If you write

$$3 = x$$

Python gives a syntax error because it thinks you're trying to redefine what “3” means.

Name examples

$$x = 5$$

x = 5

There's no output from assigning a name to a value.

x = 5

There's no output from assigning a name to a value.

Directory

Name	Value
<i>x</i>	5

It has the side effect of associating the name with the value in the program directory.

x = 5

x

Directory

Name	Value
<i>x</i>	5

x = 5

x

Directory

Name	Value
------	-------

<i>x</i>	5
----------	---

When you use the name later, Python looks it up in the directory and substitutes the value it finds.

x = 5

x
5

Directory	
Name	Value
<i>x</i>	5

When you use the name later, Python looks it up in the directory and substitutes the value it finds.

Working with names

A name can only be bound to a single value at one time.

A name can only be bound to a single value at one time.

$x = 2$

A name can only be bound to a single value at one time.

$x = 2$

A name can only be bound to a single value at one time.

$x = 2$

$x = x + 1$

A name can only be bound to a single value at one time.

$x = 2$

$x = x + 1$

Names must be given a value before being used.

```
new_name
```

```
NameError
```

```
Traceback (most recent call last)
```

```
<ipython-input-1-9d86db7a2999> in <cell line: 1>()
```

```
----> 1 new_name
```

```
NameError: name 'new_name' is not defined
```

Jupyter memory model

Pretend your notebook has a brain.

Jupyter memory model

Pretend your notebook has a brain.

Every time you run a cell with an assignment statement, it remembers that name–value binding.

Jupyter memory model

Pretend your notebook has a brain.

Every time you run a cell with an assignment statement, it remembers that name–value binding.

It will remember all name–value mappings as long *as the current session is running*, no matter how many cells you create.

Jupyter memory model

Pretend your notebook has a brain.

Every time you run a cell with an assignment statement, it remembers that name–value binding.

It will remember all name–value mappings as long *as the current session is running*, no matter how many cells you create.

However, when you open a notebook for the first time in a few hours, your previous session will likely have ended, and Jupyter's brain won't remember anything.

Jupyter memory model

Pretend your notebook has a brain.

Every time you run a cell with an assignment statement, it remembers that name–value binding.

It will remember all name–value mappings as long *as the current session is running*, no matter how many cells you create.

However, when you open a notebook for the first time in a few hours, your previous session will likely have ended, and Jupyter's brain won't remember anything.

You'll need to re-run all of your cells.

Don't delete cells defining names you want to use.

Don't use names *above* the cell with the assignment definition.

Notebooks should be a paper trail. Each cell is a record of what you've done so far.

What's in a name?

If you're ever unsure of the value bound to a name, you can simply create a new cell, type the name, and run the cell.

Python has *built-in* names, including functions like `min`, `max`, and `pow`.

Python will let you re-assign some of these built-in names, even though you probably shouldn't!

```
max = 9  
max(2, 3)
```

```
TypeError: 'int' object is not callable
```

You broke Python. What now?

If you want to restore names to their default values, do this:

1. Save your notebook
2. Restart your session

There are also some *reserved names*, e.g.,

`import`

`None`

`True`

`False`

These are so important to Python that reassigning them would be a big problem, so it won't let you do it.

Concept check

We can define the names

```
width = 400  
height = 600
```

Now if we write

```
width * height
```

it gets evaluated:

→	400	*	height
→	400	*	600
→	240000		

What if we use another name?

```
width = 400  
height = 600  
area = width * height
```

Does Python associate the name **area** with the expression **width * height** or with the number **240000**?

Writing code for people to read

“Programs must be written for people to read, and only incidentally for machines to execute.”

Hal Abelson & Gerald Sussman with Julie Sussman, *Structure and Interpretation of Computer Programs*, 1979

Choosing good names

Names are arbitrary

This is silly, but legal:

<i>five</i> = 6 five
6

<i>six</i> = 5 six
5

Names in Python are case-sensitive.

So,

Cat
CAT
cat
cAT

are all distinct names, which can have different associated values – but doing this is a bad idea because it's confusing!

They look similar – but they're all distinct!

Python is pretty flexible about what names can look like:

👍 `how_are_you`

👍 `my_AGE_is_22`

👍 `NETFLIXPASSWORD`

But it doesn't allow hyphens or other punctuation – only underscores are allowed:

👎 `this-is-bad`

👎 `worse!`

👎 `no&*way`

While names can include a number, like

👍 `pi_r_2`

They can't *start* with a number:

👎 `2_pi_r`

Every programming language also has its own *conventions* for names.

In standard Python, names are usually lowercase with words joined by underscores, e.g.,

this_is_a_good_name

thisMakesPythonCRY

Names are important!

Can you guess what this code does?

```
y = (x + 459.67) * 5/9
```

Names are important!

Can you guess what this code does?

~~$y = (x + 459.67) * 5/9$~~

temp_kelvin = (temp_celsius + 459.67) * 5/9

Choose names that are concise but descriptive.

Good:

```
seconds_per_hour = 60 * 60
```

```
hours_per_year = 24 * 365
```

```
seconds_per_year = seconds_per_hour * hours_per_year
```

Not so good:

```
i_love_chocolate = 60 * 60 * 24 * 365
```

Comments

Comments are used to explain what code does.

Good programmers write code that is *self-evident* and use comments only where necessary.

Girl on the Net

@girlonthenet@mastodon.social

Fun fact: the code which took Apollo 11 to the moon is available on github [github.com/chrislgarry/Apollo-...](https://github.com/chrislgarry/Apollo-11)

And if you look through it you'll see that - joyfully - it also includes original comments.

My absolute favourite thing about the Moon Code is that it includes comments like this: "TEMPORARY - I HOPE HOPE HOPE"
